Topic 17: Nuclear Physics

AP Physics 2

Dr. Timothy Leung January 2021

Olympiads School, Toronto, ON, Canada

Nucleus of the Atom

The Rutherford-Bohr Model

In the Rutherford-Bohr atomic model, an atom consists of

- A dense positively-charged nucleus
- Negatively-charged electrons "orbiting" the nucleus in predefined energy levels
- Most of the atom is empty space

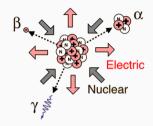

Most of the atom is empty space, although almost all the mass is concentrated at the nucleus

Nucleus of an Atom

The nucleus—where most of the mass of the atom is concentrated—are made up of **nucleons** which are:

- Positively charged protons, and
- Electrically neutral neutrons

Balancing Fundamental Forces

The nucleus of an atom is held together by balancing two fundamental forces:

- Electromagnetic force: the repulsive force between protons
 - The force drop off as the square of the distance (inverse square law)
- Nuclear strong force: short-distance force holding nucleons together
 - $\bullet\,$ Attractive between nucleons at about 1 fm (10 $^{-15}$ m)
 - Insignificant at distances beyond 2.5 fm
 - Repulsive at distances below 0.7 fm

Atomic Properties

The nucleus of an atom is identified by two numbers:

- Atomic number (Z): the number of protons
 - · Determines what element it is, and
 - its chemical properties
- Mass number (A): number of nucleons
- The number of neutrons (N) is therefore N = A Z

Isotopes

Carbon has three common **isotopes**, all with the same atomic numbers, but different number of neutrons (called "carbon-12", "carbon-13" and "carbon-14" respectively). The atomic number is sometimes omitted.

$$^{12}C$$
 ^{13}C ^{14}C

Hydrogen also has three common isotopes (hydrogen, deuterium and tritium)

$$^{1}H$$
 ^{2}H ^{3}H

On average, there are 2.6 isotopes for each element.

6

Mass of the Nucleus

The **unified atomic mass unit** $(u)^1$ is defined as 1/12 of the rest mass of a carbon-12 atom in its nuclear ground state:

$$1\,\mathrm{u} = \frac{1}{12} m(^{12}\mathrm{C}) \approx 1.660\,54 \times 10^{-27}\,\mathrm{kg}$$

The rest mass of the elementary particles can be expressed in this unit:

| Particle | Mass (u) | Mass (kg) |
|----------|-----------|----------------------------|
| Proton | 1.007 276 | 1.672614×10^{-27} |
| Neutron | 1.008 665 | 1.674920×10^{-27} |
| Electron | 0.000 549 | 9.10956×10^{-31} |

¹It replaces the "atomic mass unit" (amu) which is no longer used. The atomic mass value in the periodic table is a weighted average across all isotopes.

Mass Defect & Nuclear Binding

Energy

Mass-Energy Equivalence

One of the discoveries in special relativity² is the fundamental equivalence of mass and energy. While the derivation is based on *relativistic kinematics*, it also applies to *quantum mechanics*, from which nuclear physics is based on.

$$E = mc^2$$

| Quantity | Symbol | SI Unit |
|-------------------------|--------|---------|
| Energy | E | J |
| Rest mass of a particle | m | kg |
| Speed of light | С | m/s |

The speed of light is a universal constant: $c = 2.998 \times 10^8 \,\mathrm{m/s}$.

²Einstein, A., "Does the Inertia of a Body Depend Upon Its Energy Content?", *Annelen der Physik*, 18(13):639-641, 21 November, 1905.

Mass-Energy Equivalence

Any change in energy is *always* accompanied by a change in mass, and vice versa.

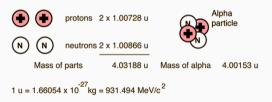

$$E = mc^2 \longrightarrow \Delta E = \Delta mc^2$$

- The concept is difficult to visualize in everyday life. Example: A baseball moving at $160 \, \mathrm{km/h}$ is more massive than a baseball travelling at $20 \, \mathrm{km/h}$, but the Δm s is too small to measure.
- But in cases when
 - speeds approaches the speed of light (v > 0.3c), or when
 - the masses are small (e.g. electrons, protons, neutrons)

the difference significant

Mass Defect

The sum of the masses of the nucleons are always higher than the mass of the nucleus itself. **Example:** the mass of the alpha particle (helium nucleus) is lower than 2 protons plus 2 neutrons:

Mass Defect

This difference in mass is called the **mass defect** Δm , which can be calculated with a simple equation:

$$\Delta m = [Zm_P + (A - Z)m_N] - m_A$$

| Quantity | Symbol | SI Unit |
|-----------------------------------|------------|---------|
| Mass defect | Δm | kg |
| Atomic number and mass numbers | Z, A | |
| Rest mass of a proton and neutron | m_P, m_N | kg |
| Rest mass of the nucleus | m_A | kg |

11

Mass Defect

Mass defect exists in any atoms because the nucleus of an atom is always in a lower energy state than the individual nucleons alone

Similar examples:

- The total energy of a planet orbiting the Sun is lower than the two objects individually
- An electron orbiting the nucleus is at a lower energy state also

Nuclear Binding Energy

The amount of energy that is equivalent to the mass defect is called the **nuclear binding** energy E_b , defined as:

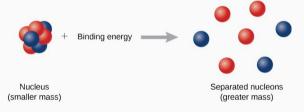

$$E_b = (\Delta m)c^2$$

| Quantity | Symbol | SI Unit |
|------------------------|------------|---------|
| Nuclear binding energy | E_b | J |
| Mass defect | Δm | kg |
| Speed of light | С | m/s |

- The energy required to break up the nucleus into its individual nucleons
- Generally expressed in *electron volts* (eV) where $1 \, \text{eV} = 1.602 \times 10^{-19} \, \text{J}$, rather than in joules

Nuclear Binding Energy

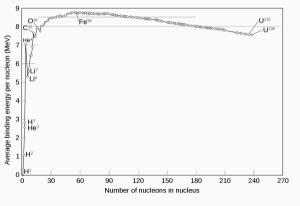

The nuclear binding energy is the amount of work required to separate the nucleons

The higher the binding energy, the more *tightly bound* a nucleus is.

Nuclear Binding Energy & Stability of the Nucleus

The nuclear binding energy is highest for iron-56 ($E_b = 492.275 \,\mathrm{MeV}$, or $8.7906 \,\mathrm{MeV}$ per nucleon)

It means that the nucleus

- requires the most energy to separate the nucleons
- most tightly bound
- most stable

To achieve greater stability in the nucleus

- Heavier atoms can split into lighter nuclei, while
- Lighter atoms can combine into heavier nuclei

Radioactivity

Radioactive Decay

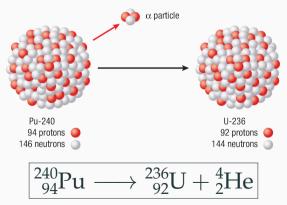

Radioactivity³ is the spontaneously disintegration of a nucleus. There are *three* types of radioactive decay:

- Alpha decay, or α -decay
- **Beta decay**, or β -decay
- Gamma decay, or γ -decay

³Or radioactive decay

Alpha Decay

In α -decay, an **alpha particle** (a helium-4 nucleus, with 2 protons and 2 neutrons), is spontaneously emitted from the nucleus. Example: plutonium-240 nucleus decays into a uranium-236 nucleus, emitting an alpha particle

General Formula for Alpha Decay

The general formula for an α -decay is shown by the equation:

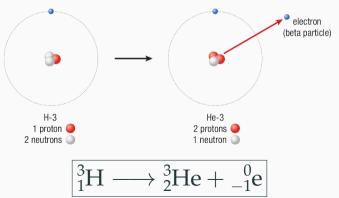

$$\begin{bmatrix} A \\ Z X \longrightarrow A-4 \\ Z-2 Y + \frac{4}{2} He \end{bmatrix}$$

The **parent atom** (X) is the reactant, and the **daughter atom** (Y) is the product. This nuclear reaction is called a **transmutation**, because the atomic number changes during the decay, and a new element is formed.

- The nuclear binding energy of the daughter atom and the alpha particle are *higher* than the parent atom.
- The combined mass of the daughter atom plus the alpha particle is *less* than the parent atom, meaning that energy is released

Beta-Negative Decay

Beta decays involve the emission/capture of a **beta particle** (electron or a positron). In beta-negative decay (β^- -decay), a neutron spontaneously decays into a proton and an electron, and the electron is ejected from the nucleus. For example, the β^- -decay of a tritiumatom is:

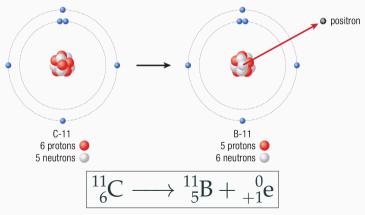

Beta-Negative Decay

The general form for β^- -decay is given by:

The daughter atom has a higher nuclear binding energy than the parent atom.

Beta-Positive Decay

In beta-positive decay (β^+ -decay), a proton spontaneously decays into a neutron and a positron. Example: decay of carbon-11 into boron-11:

Beta-Positive Decay

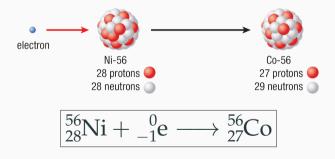

The general equation for β^+ -decay is given by:

$$\begin{bmatrix} {}^{A}_{Z}X \longrightarrow {}^{A}_{Z-1}Y + {}^{0}_{+1}e \end{bmatrix}$$

The positron released in the decay will be immediately annihilated by an electron, releasing a pair of gamma particles, each with an energy of $0.511\,\mathrm{MeV}$, moving in opposite directions:

Electron Capture

Electron capture is a form of beta decay where an electron is absorbed by a nucleus and combines with a proton to form a neutron. For example:

Electron Capture

The general equation for electron capture is given by:

$$\stackrel{A}{Z}X + {}^0_{-1}e \longrightarrow {}^A_{Z-1}Y$$

The electron that is absorbed usually comes from the lowest energy shell (n = 1, or K-shell) that is closest to the nucleus, so it is often called *K-capture*.

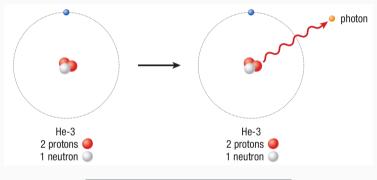

Gamma Radiation

Gamma decay (γ -decay) occurs after a nuclear reaction (e.g. α or β decay)

- The daughter nucleus is in a high-energy (excited) state
- The nucleus spontaneously releases energy in a **gamma particle** to return to a lower (therefore more stable) energy state.
- A gamma particle:
 - is a highly energetic form of electromagnetic radiation that is emitted as a **photon**
 - Has zero mass

Gamma Radiation

As an example, the γ -decay of a helium-3 atom is given by:

$${}_{2}^{3}\mathrm{He}^{*}\longrightarrow{}_{2}^{3}\mathrm{He}+{}_{0}^{0}\gamma$$

Gamma Radiation

The general equation for γ -decay is:

- The parent and daughter nuclei are identical
- Only the energy level of the nucleus has changed
 - The asterisk indicates that the parent an excited state
- Notice that the mass number and atomic number of a gamma ray $\binom{0}{0}\gamma$ are both zero.

Energies of Radiation

Radioactive particles post danger to living tissues, because

- they can ionize (or strip the electrons from) atoms
- ullet α particles have strongest ionizing ability, but can only travel a relatively short distance before becoming absorbed
- β particles and γ rays have a greater penetrating range in air and must be shielded against

| Туре | Radiation | Charge | Penetrating Ability |
|-----------------|-------------------------------|--------|-------------------------|
| α-decay | Alpha particle (He-4 nucleus) | +2 | Skin or paper |
| eta^- -decay | Beta particle (electron) | -1 | thin sheet of aluminum |
| eta^+ -decay | Beta particle (positron) | +1 | thin sheet of aluminum |
| e^- capture | None | N/A | N/A |
| γ -decay | Gamma particle (photon) | 0 | Few centimetres of lead |

Half-Life

While the radioactive decay of a single atom seems to be *random*, when there are a large number of atoms, the overall rate of decay is very predictable.

$$N = N_0 \left(\frac{1}{2}\right)^{\frac{t}{\tau}}$$

| Quantity | Symbol | SI Unit |
|--------------------------------|--------|---------|
| Amount of radioactive material | N | kg |
| Initial sample amount | N_0 | kg |
| Time | t | S |
| Half-life | τ | S |

Half-life is the time it requires for a radioactive amount to decay to half of its original value.

29

Half-Life of Radioactive Isotopes

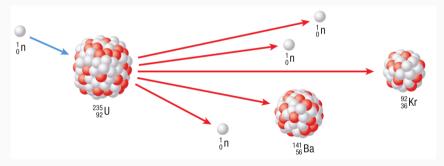

The half-life of radioactive substance can vary from a fraction of a second to billions of years.

| Substance | Half-Life (t_0) |
|--------------|-----------------------------|
| Polonium-215 | 0.0018 s |
| Bismuth-212 | 60.5 s |
| Sodium-24 | 15 h |
| lodine-131 | $8.07\mathrm{d}$ |
| Cobalt-60 | 5.26 yr |
| Radium-226 | 1600 yr |
| Uranium-238 | $4.5 	imes 10^9\mathrm{yr}$ |

Nuclear Fission

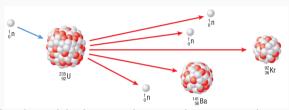

Nuclear Fission

The release of energy in a nuclear reaction primarily comes from fission, where a heavier atomic is split into lighter atoms. For example, the fission reaction of uranium-235 splitting into krypton-92 and barium-141 atoms:

$$\begin{vmatrix} 235 \\ 92 \end{vmatrix}$$
U + $\frac{1}{0}$ n $\longrightarrow \frac{92}{36}$ Kr + $\frac{141}{56}$ Ba + $3(\frac{1}{0}$ n) + energy

Nuclear Fission

- Fission reaction begins with the uranium nucleus capturing a neutron
- The additional neutron creates instability in the nucleus, causing it to split
- In splitting the atom, 3 neutrons are released from the nucleus
- The neutrons may be captured by other uranium-235 atoms, causing further reaction

Example Problem

Example: What is the energy yield of the following fission reaction?

$$^{235}_{92}U + ^{1}_{0}n \longrightarrow ^{140}_{55}Cs + ^{93}_{37}Rb + 3 (^{1}_{0}n)$$

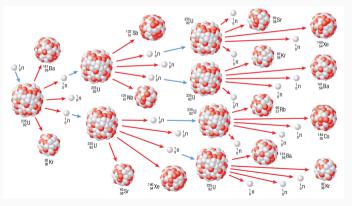

$$m(U-235) = 235.044 \text{ u}$$

 $m(Cs-140) = 139.909 \text{ u}$
 $m(Rb-93) = 92.922 \text{ u}$
 $m(n) = 1.009 \text{ u}$

Chain Reaction

A chain reaction is a series of reactions that can repeat over several cycles

- Reactions occur without requiring any material being added to the system
- The amount of fuel required to cause a chain reaction is called critical mass

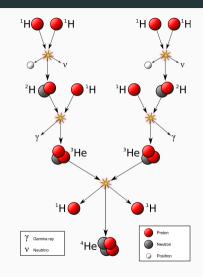

Nuclear Fusion

Proton-Proton Reaction

The simplest fusion reaction occurs under high temperature about 4×10^7 K is the proton-proton chain. In most the basic form, it is written as:

$$4 \left(^1_1 H \right) \longrightarrow {}^4_2 He + 2 \left(^0_{+1} e \right) + \mathsf{energy}$$

In each p-p reaction, 26.732 MeV is released. The exact mechanism for the p-p chain is shown in the right.

CNO Cycle

A fusion reaction that occurs in even higher temperatures (between 1.5 to 1.7×10^7 K) is the carbon-nitrogen-oxygen (CNO) cycle. The total energy released in one cycle is 26.73 MeV.

• The core temperature of the sun is about 1.56×10^7 K, so only 1.7% of helium-4 nuclei produced in the Sun are from this process
